The Disturbance Theory Do Not Disturb!
Richard Windows STRI Turfgrass Agronomist

A really great article from Richard Windows on how the perennial grasses like fescues and bents really need time to establish. Obviously, most of the examples in his article are based on links open championship courses. This data and the parameters given cannot be transferred on a 1/1 bases to other golf courses. Mostly however, the principle requirement of low disturbance for the successful establishment of Fescues and/or Agrostis species remains constant.

Before using the Disturbance Theory, at first problems in the rootzone such as thatch, black layer, layer formation, drainage and compaction must be eliminated.

Putting surfaces, dominated by the bents and fescues, provide consistent year round surfaces. Unfortunately, many of our greens continue to be dominated by annual meadow grass. A recent survey conducted by all STRI agronomists in the UK and Ireland for the R&A, proves this is the case. The results showed the average species composition in our golf greens in 2005, to be 56% annual meadow grass, 32% bent, 7% fescue and 5% perennial ryegrass/Yorkshire fog. Out of 598 courses assessed, 75% had greens supporting more than 50% annual meadow-grass. The annual meadow-grass dominance, makes our greens vulnerable and inferior during the winter. This information shows how many courses may be failing to reach their potential. History has always blamed excessive fertiliser and water applications, to be the main cause of annual meadow-grass dominance in our greens. I used to as well, until I considered the ecology of the grasses involved the article “Changing the Nature of your Greens” explains this in more detail. In summary, annual meadow-grass enjoys disturbance, while the finer grasses flourish in a more settled environment. Annual meadow-grass, is so successful in golf greens because the environment is so disturbed or being constantly damaged. Disturbance pressure comes from surface preparations and of course play. In this article, we examine the effect of surface preparations on sward composition. The aim is to help you think about the preparation of your greens a little differently.

The true cause of annual meadow-grass ingress, comes from the creation of gaps in the turf. Constant physical damage (or disturbance) of the grass plant, creates these gaps. Modern greenkeeping practices and their mechanisation, have radically increased the disturbance pressure imposed on fine turf. We now mow incessantly and verticut and groom in an attempt to please the ever more demanding modern golfer. While such aggressive practices are done for the right reasons, they might, in the end, be causing untold harm. The symptoms can be seen, when the turf thins and the soil surface is exposed. Annual meadow-grass is adapted to exploit these conditions. It may therefore be true to say, the misuse of the triplex mower and modern turf refinement tools, are one of the main reasons for annual meadow-grass dominance in our golf greens.
Before we had these ultra efficient tools, the amount we refined our greens was restricted by time and the physical constraints of the human body. For instance, it took a long time to mow
greens with a pedestrian mower and even longer when using a push mower or scythe! Not to mention the physically demanding nature of the work. This meant it was largely impossible to over-manage and over-disturb putting greens. Consequently, the golf green environment was settled, which allowed the fine grasses to dominate. Fertiliser and water were kept to a minimum, as over-application simply made the grass grow faster! Greenkeepers knew the surface would be inferior, if grass growth was rapid. Growth was the last thing they wanted. A settled, undisturbed and unproductive environment, suited the finer grasses. It also produced the best year round putting surfaces. Old Tom Morris understood this.

The tranquillity of this settled and unproductive environment, was forever interrupted with the introduction of the triplex mower around 1968. Suddenly, greens could be mown in a fraction of time, meaning they were done so more regularly. They were even mown when it was not necessary! Further technological advances allowed the machines to follow contours, which facilitated ever closer mowing. In essence, triplex mowing increased disturbance pressure on the turf.

Soon after the triplex mower, came the introduction of more efficient and effective turf refinement tools. These mechanical tools, with their motor driven rotating steel blades (now with tungsten tips); were much more aggressive than the bristles of a brush - you can almost see the fine fescue and bent turf quivering at the prospect! Their ease and efficiency of use allowed the frequency of operation to increase. The result was increased disturbance pressure on the turf.

The use of the triplex mower and more efficient turf refinement tools, gave golfers the faster surfaces they demanded. However, little regard was given to their damaging effect on our fine turf. To put it simply, the fine fescue and bent could not cope with the damage. Consequently, the sward began to thin and gaps were created. Annual meadow-grass exploited these gaps - the invasion had begun. To help the thin and damaged turf recover, more fertiliser and water was applied. The annual meadow-grass thrived in this more disturbed and productive environment. Our fine turf putting surfaces began their decline and many would never be the same again. The era of aggressive surface preparation and high input greenkeeping had (to our shame) arrived.

Many greenkeepers ignored the trend of more aggressive surface refinements. They knew it wouldn’t make their surfaces any better. To this day, courses that have upheld austere greenkeeping principles, continue to provide the best putting surfaces. The greenkeepers charged with the management of these courses, still follow what Old Tom did all those years ago. They know the slow growing fine fescue and bent grasses, only require gentle refinement to produce high quality putting surfaces. While modern machinery is used, it is used with great caution. For instance, verticuting is implemented occasionally and only when the fine grasses
are growing strongly. The greens are never scalped. Fertiliser and water, are always kept to a minimum - as over application will only require more aggressive refinement. Consequently, these environments remain settled and unproductive, which is why the fine grasses continue to flourish. Old Tom Morris taught us this approach. We now call it “traditional greenkeeping”.

The results of traditional greenkeeping were once again highlighted to the international golfing fraternity, during the 2005 Open Championship played over the Old Course, St. Andrews. During the Championship, the greens were maintained at 4.5 mm. Mowing was omitted when it was not necessary - the slow growing fescue and bent, simply did not need to be mown every day. Light brushing, light top dressing, a little rolling and May verticutting was sufficient to provide over 10.5 foot on the Stimpmeter and smooth true ball roll for the world’s best players. Contrast this to the normal maintenance for Major championships, when the greens are scalped two or three times a day! It is obvious which grass this will promote.

I have perhaps blamed the triplex mower and modern turf refinement tools rather unfairly, as they are, of course, great innovations and have improved the quality and efficiency of surface production. Of course the problem does not lie with the machines but the way in which we use them. All too often they are used too frequently and too aggressively. Such misuse increases disturbance pressure on the turf. When the pressure becomes too great, the turf thins and gaps are created and annual meadow-grass invades. To help the turf recover from the pressure, requires a heavier hand with the fertiliser bag and irrigation sprinklers. It is this combination of disturbance and greater productivity, that leads to annual meadow-grass dominated greens.

I have no doubt that the production of better putting surfaces can be achieved by the promotion of the finer grasses. To be successful in this aim, we must adapt our management practices to minimise disturbance and reduce productivity. In essence, the way in which we prepare our surfaces must become less aggressive. This is not too difficult to achieve so let me describe some simple strategies...

• Reduce mowing frequencies. Ask yourself - do you really need to mow all the time? Can occasional operations be missed?
• Raise the height of cut. Every greenkeeper knows what height is comfortable and stress free for their turf. You should go no lower than this height. Do not push the limit of your turf it simply will not cope.
• Miss out the final perimeter cut a couple of times a week. The perimeters of the greens are where we see the first symptoms of excessive disturbance. Never engage groomers or verticutters on this perimeter pass.
• Relax verticutting and scarification. Consider brushing or light grooming, to gently refine the turf. When verticutting or scarification is necessary, ensure the finer grasses are growing strongly to aid rapid recovery and follow with bent/fescue overseeding, to encourage the restoration of full grass cover. Under no circumstances scarify when annual meadow-grass is seeding.
• Increase top dressing frequencies to smooth and firm the surface, as well as diluting the thatch. Avoid harsh operations to work the material off the surface. This hurts your turf.
• Use rollers or a Turf Iron to provide a little extra pace and smoothness when required. This will ensure the greens can be maintained at a higher cutting height.
• Increase hand mowing instead of triple mowing, as it causes less disturbance and allows you to closely monitor the environment.

The true reason for annual meadow-grass ingress into our fine turf putting surfaces, was the creation of gaps in the turf. Aggressive surface preparations were one way such gaps were created. Excessive inputs of water and fertiliser were applied to restore the cover after damage. This created a productive and highly disturbed environment, in which annual meadow-grass thrived and dominated. The current era of aggressive high input greenkeeping, continues to promote this undesirable species. To restore the dominance of the finer grasses, we need to provide a more settled and less productive environment. To do this, we will have to prepare our surfaces differently but not to the detriment of the playing quality. The key to this strategy is the minimisation of disturbance. This means being less aggressive with your surface preparations, by more cautious use of the triplex mower and modern turf refinement machines. With this approach, you will soon see the finer grasses returning to your greens.

The misuse of irrigation delivery, is one of the reasons for the decline of the finer grasses on UK golf courses, over the last 40 years. This, alongside the arrival of the triple mower and compound fertiliser in all its forms, spelt disaster for the bents and fescues. The production of softer and lusher turf, made the game easier and also happened to suit the TV companies who could send appealing ultra green images into our living rooms. The “green is god” age had dawned and we quickly descended into agronomic oblivion to drown in a sea of Poa annua!

So, how do we set about righting the wrongs and creating the correct environment for our preferred grasses? Well, the very tool that partly initiated the decline, could be the salvation. Irrigation is the most powerful agronomic tool, providing it is used correctly.

In the article “Changing the Nature of Your Greens”; the argument is made that unnecessary disturbance, is the main reason for the loss of finer grasses on our golf greens. We have inadvertently created an environment more suited to opportunistic grasses such as annual meadow grass (Poa annua) by feeding and watering and then having to use aggressive disturbance techniques to create the playing surface. The finer grasses simply cannot cope with intensive disturbance, whereas Poa annua likes nothing better.

Greenkeeping requires a basic knowledge of the ecological strategies, of the two or three major grasses. Success will come, if we create the right environment for the finer grasses to flourish. In summary, the fine bent and fescue, enjoy settled and unproductive environments, while the annual meadow-grass dominates when productivity and disturbance pressure is high. By understanding these simple ecological strategies, we can easily reverse the botanical decline of our putting surfaces, experienced during the last century. We need to move away from high input and aggressive greenkeeping practices. One of the key tools in this process, is the correct use of irrigation. Believe me, if we get this right, the finer grasses will return and we will restore the true enjoyment of real golf.

Let us consider two scenarios. The first is the classic annual, meadow grass dominated surface. It has been over fed and overwatered for years, with two inches of thatch residing at the base of
the turf. The summer surfaces are satisfactory but the winter surfaces become soft and disease ridden. To improve turf and playing quality here, we must reduce the productivity of the environment, by minimising irrigation and fertiliser inputs. At the same time, we must create the right soil conditions, in which the fine grasses can flourish by removing the thatch. This improves the firmness of the surface and reduces the need for excessive disturbance, which creates the more settled environment. When reducing productivity, a gradual approach is required, as radical reductions in irrigation or fertiliser inputs will excessively compromise playing quality.

The second scenario is a sward dominated by both bents and fescues with some annual meadow grass contamination. Here the objective is to retain the dominance of the fine grasses. We do this by exerting controlled stress on the shallow rooted annual meadow-grass, by tight regulation of irrigation to stop it gaining advantage. To help achieve this objective, we can be even more hard-line with irrigation inputs towards the late summer, to further reduce the competitive ability of the annual meadow-grass before bent/fescue overseeding.

In both scenarios the aim is to create a more settled and less productive environment as possible. At the appropriate time, irrigation application should be relaxed to exert the necessary stress, to reduce the competitive ability of the shallower rooted annual meadow-grass. As the fine grass component of the turf increases, greater stress can be exerted as the water requirement of the turf naturally decreases.

Proper irrigation is ultimately powerful in the restoration of fine turf surfaces. We use it to favour the strengths of the deep-rooted fine grasses and exploit the weaknesses of the shallow rooted annual meadow-grass. Managing irrigation correctly, will restore the dominance of the fine grasses and provide golf surfaces commensurate with the heritage of our game.

The level to which irrigation is applied, is of course the main challenge. This will reduce as we optimise delivery and maximise water penetration. In this day and age it is critical that applied water is fully utilised by the sward and not wasted. How much or how little do we apply? Well this is the $64,000 question. I do not believe this can be taught in a classroom. Every site is different, every green is different and every square metre of turf is different. Trying to measure these differences empirically and come up with a “one size fits all solution” is fatuous. Trying to implement this approach will in all likelihood lead to further decline in turf standards. There is no doubt effective irrigation delivery, is an art not a science. However, there is one over riding principle - water should only be applied to keep the turf alive and the surface uniform - nothing else!

Successful irrigation management can only be achieved by the correct deduction of the greenkeeper. There is no replacement for a good man with a sound knowledge of his site. The head man should know far better than any computer or tensiometer how much water is needed to keep the turf alive, to facilitate agronomic improvement and to optimise playing quality. If we are going to restore the fine grass content of our greens the golfers must trust the judgement of the greenkeeper.
Irrigation application is not just about pressing the button on the automatic system. This approach will generally lead to agronomic deterioration. We must create a healthy dry surface rather than a lush and vibrant one. To help with this we must ensure the water we applied can penetrate into the ground. This is aided with the use of wetting agents combined with regular aeration. What is more, many clubs have great success with water injection aeration using the Hydroject. Not only does this aerate the soils but it also supplies water to the deeper rooted grasses giving them a greater competitive edge over the shallower rooted annual meadowgrass.

The irrigation systems of today are great and sophisticated tools but they are a disaster waiting to happen in the wrong hands. There have been too many wrong hands operating over the last forty years hence the decline of the fine grasses on our courses. We have a duty to correct this and re-establish the link between the grass upon which we play the game and the game itself. Our golfing heritage largely depends on correct irrigation.

It’s not what you think
In these times of healthy debate, chew on this thought...
...You don’t have to starve your turf to favour the development of the finer grasses. Fertilising to favour the finer grasses is more about not over-fertilising than adopting a starvation strategy. The aim of this article is to get you formulating your fertiliser programme with the needs of the finer grasses in mind. With a predominance of the bents and fescues, we achieve better quality surfaces throughout the year.

The downward spiral
The problem is that too much fertiliser forces you to rely on intensive verticutting and aggressive mowing to prepare firm, fast and true playing surfaces. Hollow tining and deep scarification, become necessary to get rid of the deeper thatch. It is this incessant damage that the finer grasses can’t stand. Such an aggressive method of preparing putting surfaces, will inevitably require additional fertiliser applications to ensure that the turf recovers from the onslaught. It is constant disturbance coupled with high productivity that brings annual meadow grass dominance.

This is it
We try to minimise fertiliser inputs to reduce the need for disturbance. A more settled and less intensively managed environment will give the bents and fescues a fighting chance. A less disturbed environment will also take some stress to allow you to weaken the annual meadow grass. Let me tell you about fertilising golf greens, to favour the finer grasses.

Step back and think. When greenkeeping, our single objective is to create playing surfaces of the highest possible quality. If that means we want to favour a predominance of the finer grasses, we will have to set the correct environment. Ultimately, this should involve minimising the level of disturbance, which is why
we reduce fertiliser inputs. We then impart controlled beneficial stress at some point during the
summer to pressurise the annual meadow grass at a time of overseeding, to let the finer grasses
take advantage. We impart this stress with judicious irrigation rather than fertiliser because it is
easier to control. We generally try to keep irrigation inputs to a minimum to prevent thatch
accumulation but we only use it to actually lever stress for a short period. This will serve to
weaken the annual meadow grass before the new seedlings emerge. Too much stress for too
long weakens all the grass species and golf greens are too busy to be weak. See “Changing The
Nature of Your Greens” on for more detail.

Just enough
So, we want to minimise fertiliser inputs to reduce the need for incessant aggressive
treatments. Minimal (some would say “optimal”) means producing just enough growth for the
surface to be prepared and be able to withstand play without deteriorating. The desired level of
growth will vary depending on what we need to achieve at different times of the year. For
example, during spring we will need to generate a certain level of growth to bring recovery from
winter wear and to allow the early season preparations to take place. During the summer, once
we have set-up our surfaces, we would want to keep growth quiet to reduce the need for any
further aggressive treatments. Into autumn we must ensure that the turf is strong enough to
withstand and recover from the end of season renovations prior to the onset winter dormancy.
When minimising your fertiliser inputs concentrate on finesse and timing. The old boys used to
feed by hand, to allow localised areas to be missed-out or receive extra nutrient depending on
the turf condition - now that is finesse! Essentially, you should only apply what is necessary and
no more.

Nitrogen
In terms of nitrogen input, for soil-based greens the Danish experience finds 5 - 7 g/m2 N per
annum to be sufficient. You should aim to apply as little as necessary so you don’t have to
verticut too often through the summer. Be careful when weaning greens off a high-N approach
because there may be an adverse reaction in the form of disease attack. Just take it steady and
trust your judgement, that’s all.

In most cases the main source of nitrogen should be ammonium sulphate for its acidifying
effect. The finer grasses can tolerate a pH below 5.5 whereas the annual meadow-grass cannot.
Nutrient availability and microbial activity are factors here but not in this article. Generally,
lowering the pH is a way of selecting-out annual meadow-grass. Sulphate of ammonia should
represent roughly 75% of the total nitrogen.

The remaining nitrogen can be balanced up with lesser amounts of dried blood for prolonged
release or urea-based liquids during the summer months. Don’t use too much organic nitrogen
as this will promote disease prone lush growth and don’t be fooled into using nitrates for the
same reason. Disease equals disturbance and plays into the hands of annual meadow-grass. Just
try to minimise nitrogen inputs, to reduce the need for disturbance.
Fescues will flourish in a high pH but annual meadow grass dominance can only be avoided with the influence of an overriding environmental stress, such as raised salinity or droughting. Liming generally plays into the hands of the weeds, worms and diseases.

Phosphate
The results of research on the effect of phosphate applications on fine turf quality, have actually been inconsistent. Incessant phosphate fertiliser applications undoubtedly encourage the development of annual meadow-grass but at lower levels the relationship is not so clear-cut. Regular phosphate applications will create an ideal turf base for seed germination to the advantage of the annual meadow grass. Just don’t lose your head about phosphates and remember that they are not usually necessary to favour the bents and fescues. It is my feeling that the famous rabbit urine scorch tale should have been interpreted as scorch disturbance laced with urea fertiliser to encourage annual meadow-grass invasion rather than as being the direct effect of high phosphate levels.

Potassium
Potassium is more mobile and might well need supplementing on sandier soils. Potassium certainly has benefits in terms of drought and disease tolerance but don’t hang all your hopes on it. Monitor potash levels on an annual basis if there is any doubt. Just remember that favouring the finer grasses is all about managing minimal disturbance.

Keep it simple
So, what does this mean in terms of your fertiliser programme? As an example you could kick off growth in spring with an application of lawn sand. This should be applied with the onset of spring growth and will generate recovery from winter wear. An application of 8:0:0 or 8:0:6 fertiliser could then be made when strong spring growth is established. This growth will allow the early season preparations to take place. Using sulphate of ammonia based feeds during the spring will discourage annual meadow grass from invading gaps within the sward by lowering the surface pH. Liquid feeds can then be applied occasionally during the summer months, to sustain healthy rather than lush growth. Seaweed soil conditioners may be tank mixed in with liquid feeds if it is felt that they have a beneficial effect. Finish off in the autumn with an application of a turf hardener type product (2-0-2 or 3-0-3 plus Fe or similar) to strengthen growth and harden the sward against disease attack. The rate of applications should be as little as necessary. Your fertiliser programme should be focused on controlling growth so you don’t need to employ consistently aggressive surface preparation techniques.

Surface preparations
So, how do we prepare surfaces without incessant verticutting or employing ever-lower heights of cut? Apply heavy top dressings with spring growth to firm and true-up the surfaces. A certain amount of verticutting will be necessary at this time but don’t be unduly aggressive or too frequent. Once the surfaces are prepared we should then be aiming to let them be. We
maintain our firm, true and smooth surfaces without undue growth by brushing, with light in-
season top dressings, rolling, maintaining sensible heights of cut and employing isolated light
verticuting if necessary.

Regular top dressing has the added benefit of keeping the turf base sandy and unattractive for
annual meadow-grass seed germination.

Less is more
If you want to fertilise for the finer grasses, you should be thinking in terms of minimising the
need for aggressive surface treatments. You will need strong growth to prepare your surfaces in
spring but from then on try to let them go to nature. Your job is to find the minimum growth
level possible for you to be able to sustain quality surfaces without incessant verticuting. Ask
your fertiliser supplier to concentrate on this when making recommendations based on soil
analysis results.
The finer grasses are tender souls that don’t like incessant rough treatment but they can
withstand stress. Remember, at no point do we withhold fertiliser to exert stress. We exert
stress on the annual meadow grass for a limited period in summer, by controlled droughting in
conjunction with overseeding to give new seedlings a chance to take hold. Be patient and stick
to your principles and the finer grasses will come.
Get this thought into your head...
...Aggressive greenkeeping is the death of the finer grasses.
